

Fermionic Mediators, Static Potentials, and Contact/Boundary-Condition Limits

Abstract

The textbook derivation of a static potential from “field exchange” uses a bosonic mediator linearly sourced by a commuting classical density, yielding an effective action quadratic in the source and (in a static limit) a central Yukawa/Coulomb potential. This derivation does not transplant verbatim to fermionic fields: the linear source terms for fermions require Grassmann-valued sources, so there is no ordinary commuting classical source whose elimination produces a classical potential in the same way. This note isolates the precise obstruction and records the robust infrared replacement: when a microscopic description reduces to local operators at low resolution, the effective interaction is encoded by contact terms (delta kernels and their derivatives) or, equivalently, boundary-condition/self-adjoint-extension data, with renormalization-group running when the contact limit is singular.

This is a dependent note aligned with the repository’s “refinement compatibility” program: contact terms are diagonal-support kernels, and their scale dependence is a compatibility condition rather than an afterthought.

1. Purpose and scope

This note answers a narrowly phrased question: what can it mean for a **fermionic** field to “generate a (central) potential” in the same sense that a massive bosonic field generates a Yukawa potential?

We keep the scope bounded: 1. state the bosonic sourcing \Rightarrow potential mechanism (derivation-first, brief), 2. state the fermionic obstruction precisely (Grassmann sources), 3. give one explicit IR matching witness: **local operators** \Rightarrow **contact/derivative-contact kernels**, 4. connect contact kernels to the repo’s point-interaction/RG witnesses.

We do **not** claim that fermions cannot affect forces; we only isolate which parts of the “classical source \Rightarrow potential” story fail, and what the correct replacement statement is at low resolution.

2. What “a field generates a potential” means in the bosonic source story

The archetypal construction is a bosonic mediator φ linearly coupled to a commuting source $J(x)$:

$$S[\varphi; J] = \int d^D x \left(\frac{1}{2} \varphi K \varphi + J \varphi \right), \quad K = (\square + m^2) \text{ (example)}.$$

Integrating out φ (Gaussian elimination) yields an effective action quadratic in the source,

$$S_{\text{eff}}[J] = -\frac{1}{2} \int d^D x d^D y J(x) K^{-1}(x, y) J(y),$$

so the static, nonrelativistic limit of K^{-1} produces a central potential (Yukawa for $m \neq 0$, Coulomb-type when $m = 0$).

The key structural ingredient is that the source is an ordinary commuting function (a classical background density).

3. Fermionic fields: linear sources are Grassmann, so the classical-source story does not transplant

For a Dirac fermion Ψ , the generating functional with sources is written with **Grassmann-valued** sources $\eta, \bar{\eta}$:

$$Z[\bar{\eta}, \eta] = \int D\bar{\Psi} D\Psi \exp \left(i \int d^D x \bar{\Psi} (i\gamma^\mu \partial_\mu - m) \Psi + i \int d^D x (\bar{\eta} \Psi + \bar{\Psi} \eta) \right).$$

An explicit statement of this form, including that $\eta, \bar{\eta}$ are Grassmann-valued, is recorded in [Floerchinger2024QFT1Lecture21].

Two immediate consequences follow.

Remark 3.1 (Obstruction statement). The bosonic derivation “choose a commuting classical source J , integrate out the field, and read off a classical potential” does not directly apply to fermions, because the linear source terms that couple to Ψ require Grassmann sources rather than commuting c-number densities. Therefore, “fermion exchange generates a classical potential between commuting sources” is not a well-posed transplant of the bosonic story.

This does **not** mean fermions are irrelevant: fermions can and do affect effective interactions through loop effects, through bosonic composite modes (bilinears), and through low-energy EFT operators. The point is that the meaning of “generates a potential” must be stated through one of these controlled mechanisms.

4. IR replacement: local operators \Rightarrow contact kernels / boundary-condition data

At low resolution, integrating out heavy degrees of freedom typically produces local operators. In a two-body, nonrelativistic sector, this appears as an amplitude expansion analytic in momentum transfer q :

$$\mathcal{A}(q) = C_0 + C_2 q^2 + O(q^4).$$

The coordinate-space interaction associated to such an analytic expansion is distributional and diagonal-supported. The invariant core is a Fourier-transform identity:

$$\int \frac{d^d q}{(2\pi)^d} e^{iq \cdot r} = \delta^{(d)}(r), \quad \int \frac{d^d q}{(2\pi)^d} q^2 e^{iq \cdot r} = -\nabla^2 \delta^{(d)}(r).$$

Derivation 4.1 (Contact expansion gives $\backslash(\backslash delta\backslash)$ and derivative contacts). Interpreting the low-energy interaction kernel as the inverse Fourier transform of $\mathcal{A}(q)$ (Born-level language, up to overall convention-dependent factors), we obtain

$$V(r) \propto \int \frac{d^d q}{(2\pi)^d} e^{iq \cdot r} \mathcal{A}(q) \propto C_0 \delta^{(d)}(r) - C_2 \nabla^2 \delta^{(d)}(r) + \dots.$$

Thus locality at low energy naturally becomes **contact data**: delta kernels and their derivatives supported at a point (or on the diagonal, in kernel language).

In singular cases (notably δ interactions in $d \geq 2$ in various channels), this contact data is not simply a fixed number: it is defined by a renormalization condition and can generate RG-invariant scales and bound states [Jackiw1991DeltaPotentials] [ManuelTarrach1994PertRenQM].

5. Boundary-condition reading (point interactions)

Point-supported interactions can be encoded as self-adjoint extension / boundary-condition data rather than as ordinary functions $V(r)$. This is the natural operator-theoretic counterpart of “diagonal-support kernels.” For standard references and pedagogical framing, see [BonneauFarautValent2001SAE] and the delta-potential discussion in [Jackiw1991DeltaPotentials].

This viewpoint matches the repo’s “controlled refinement” theme: when a continuum description is defined as a refinement limit, UV data can survive in the limit precisely as boundary-condition parameters (contact terms), with RG flow expressing compatibility across resolutions.

6. Outlook (kept minimal)

Longer-range effects associated to fermionic degrees of freedom can arise through loop-induced mechanisms or through emergent bosonic composite modes. Treating those responsibly would require a separate bibliography-hardening pass and is outside this note's scope.
